Nanoplastic, Mineral, Groundwater, Adsorption

Abstract

The ever-increasing plastic production and its continuous release of primary and secondary nanoplastic particles (NP) (particles <1000μm) to the environment is an emerging contaminant for terrestrial environmental systems. Its fate and transport characteristics in the subsurface are still not fully understood, as those environments are highly complex with high mineral, chemical, biological and morphological heterogeneity. Our study focuses on the interaction between major abundant minerals occurring in the subsurface and NP under simplified water chemical conditions (1mM KCl, pH 5.5). Therefore, potential chemical effects from ions in solution can be excluded, and only the effect of mineral complexity can be assessed. Various surface-modified polystyrene nanoparticles serve as proxies for degradation (-COOH) or protein associations (-NH2) occurring in plastics in environmental settings. Here, we also compare our experimental results to DLVO double-layer force estimates. All minerals studied maintained negative charges across pH changes. Therefore, we hypothesize that adsorption behaviour is mainly "surface charge" driven (Zeta potential). Furthermore, we discuss other mechanisms, such as specific ion-binding interactions occurring in the presence of metal ions, bridging mechanisms and hydrogen bonding. Our study indicates that biogeochemical and mineralogical composition is a controlling factor in NP attachment and release processes in subsurface environments and, thus, crucial for transport in aquifers.

2

1. Introduction

Plastic particles follow complex transport behavior along various environmental pathways with different transport mechanisms according to their size range, solution chemistry and biogeochemical conditions. Nano-sized plastic particles (NP) (particles <1 µm) introduce additional considerations in plastic transport as their size increases the importance of particle-particle interaction and particle-collector grain interaction in the fate of plastic. Similarities between NP and engineered nanoparticles (ENP) transport exist once material-specific properties (density, aggregation behavior, hydrophobicity, surface reactivity) are accounted for (Koelmans et al. 2015). Yet, NPs differ greatly from ENPs in their particle morphology and compositional diversity. (Gigault et al. 2021). NP transport follows water cycle pathways and deposits via atmospheric precipitation, transports via surface waters (streams, sewage channels, etc.), or agricultural practices (plastic mulching), and eventually infiltrates shallow soils to reach groundwater aquifers through recharging water (Allen et al. 2019; Bergmann et al. 2019; Bläsing and Amelung 2018; Dris et al. 2015; Hurley et al. 2018; Kirstein et al. 2021; Mintenig et al. 2017; Nizzetto et al. 2016; Vollertsen 2017).

NP deposition in shallow soil is highly likely due to its complex hydrology (wetting-drying, dual porosity matrix) and biogeochemical characteristics, supporting particle retention in the shallow subsurface (Bläsing and Amelung 2018). It has been shown that pollutants and ENP infiltrate beyond shallow soils and enter the saturated zone via dominant convective transport through coarser porous media, matrix heterogeneities, well-connected macro or micropores and preferential flow paths, which develop along fractures and cracks (Kessler et al. 2012; Looms Zibar et al. 2018; Mosthaf et al. 2021). An effective filtering and physical retention process for particles is "straining" in saturated pore water. Straining is mainly a function of grain size distribution and the ratio between particle-collector grain sizes (i.e., minerals). Straining occurs until a critical ratio between the particle-collector grain size does not exceed 0.05 to 0.002 (Bradford et al. 2002; Herzig et al. 1970). As an example, if 100 nm NPs are released into saturated subsurface materials, grains in the matrix as small as 2 µm and as large as 50 µm are expected to induce straining. Groundwater aquifers, which aim to

3

59   produce a cost-effective water yield, contain hydraulic conductivity beyond the fine sand range and,

60   therefore, in return, have grain size distributions and mean grain sizes, producing straining ratios far

61   above the straining thresholds. Additionally, fractures or macropores in consolidated soils and

62   aquitards may exceed those thresholds (Beven and Germann 1982). Therefore, straining becomes

63   ineffective and leaching of nanoplastic particles <100 nm can be expected. Consequently, other

64   mechanisms, such as the chemo-electric properties of particles and minerals at the submicron scale,

65   become important for the transport of NPs.

66   Groundwater aquifer systems are foremost characterized by their complex mineral composition. As

67   such, minerals are a major component of the subsurface aqueous environment and pose a large

68   cumulative reactive surface. The mineral composition of an aquifer is governed by its geological

69   evolution. Carbonates, clay minerals from the smectite, illite and kaolinite groups, quartz and other

70   rock-forming silicates, as well as iron oxides, are among the most abundant minerals of the Earth´s

71   crust and hence are expected as the most dominant minerals in terrestrial aquifers. Recently,

72   molecular dynamic simulations have also shown the great potential of the hydroxyl surfaces of

73   kaolinite to bind emerging contaminants of PFAS molecules (Loganathan and Wilson, 2022). Clay

74   minerals and phosphate, i.e., apatite, are also known to adsorb to metal contaminants (Zhuang and

75   Yu 2002; Li et al. 2023). Calcite and the Al- groups of feldspar effectively adsorb arsenate (As V)

76   (Alexandratos et al. 2007; Sø et al. 2008; Yazdani et al. 2016). A surface modification of the iron-

77   bearing silicate mineral biotite to nano FeC_2O_4 has also shown high removal potential for Cr(VI) and

78   Cr(III) pollution under environmentally relevant conditions (Zeng et al. 2020). Iron oxides, in particular

79   goethite, are known as an effective adsorbent for heavy metals and other inorganic components (i.e.,

80   fluor) or a range of organic compounds, i.e., glyphosate (Dideriksen and Stipp 2003; Liu et al. 2014;

81   Borch et al. 2010). In addition, a wide range of studies exists on the retention capacity of different

82   minerals and natural soils for various ENPs, such as TiO_2, ZnO_2 or AgNPs (Mustapha et al. 2020;

83   Dong and Zhou 2020; Parsai and Kumar 2020; Coutris et al. 2012; Rahmatpour et al. 2017; Simonin

84   et al. 2021; Torrent et al. 2019; Manik et al. 2023), to name a few. Recently, polymer-based NPs and

85 their effect on subsurface systems have moved into focus (i.e., Yu and Flury 2020), making NP

86 interactions with subsurface geochemistry and mineralogy pertinent to NP fate.

87 Most minerals maintain a negative surface charge under environmentally relevant conditions in

88 freshwater systems (Kosmulski 2009). A few minerals, such as iron oxides, have predominantly

89 positive surface charges, favoring the attachment of negatively charged plastic polymers (M. Li et al.

90 2019). However, NP's aggregation and retain-release process strongly depend on the particle

91 surface's physiochemical conditions and surrounding solution chemistry. (Elimelech 1994).

92 Aggregation behaviour is often studied under batch experimental conditions, where particle size is

93 measured over time under varying solution chemistry, and a time-resolved size increase is used to

94 derive attachment-efficient parameters (Chen and Elimelech 2006; Alimi et al. 2022). Zhang et al.

95 (2020) describes adsorption between NP, goethite, aluminum oxides, and kaolinite in batch-scale

96 studies and point to the dependence of adsorption on surface charge and solution pH. However, to

97 date a lack of studies focused on other regularly occurring minerals to address subsurface

98 complexity remains, which we aim to address in the current study.

99 This study investigates whether the subsurface acts as a sink for NP due to mineral-plastic

100 interaction alone. To this end, we i) investigate the chemo-electric properties of NP and minerals

101 under changing solution pH conditions and ii) study adsorption behavior in batch adsorption

102 experiments.

5

2. Methods:

2.1 Materials:

Non-functionalized pure polystyrene particles (PS-PLAIN) and carboxyl- functionalized polystyrene (PS-COOH) of 100 nm nominal diameter were purchased from Micromod (Micromod Partikeltechnologie GmbH, Rostock). Carboxyl-coated polystyrene is a proxy for degraded plastic, as carboxyl groups are produced at nanoplastic surfaces via ageing by UV light. (Mao et al. 2020). Amine-coated polystyrene (PS-NH2) of 100 nm nominal diameter was purchased from Sigma Aldrich and represents a proxy for the interaction of plastics with organic nitrogenous substances typically present in the subsurface. The polymers were analyzed using ATR-FTIR to confirm their chemical surface composition (**Error! Reference source not found.**). A stock solution of 1000 mg/L was prepared from the vendor's Stock suspension (10000 mg/L) for each PS type. For the experiments, a fraction of the stock was diluted with one mM Potassium chloride (KCl) to achieve the desired experimental particle concentration of 20 mg/L. The experimental PS concentrations used here are far beyond realistic environmental concentrations. Still, high concentrations were chosen to achieve mechanistic understanding and avoid the potential influence of uncertainty of analytical methods used herein at low concentrations. The three different particle coatings provide proxies for ions and physio-chemical conditions (i.e., charge) to which plastic polymers can be exposed in natural environments. Pure polymers are unlikely to occur in natural environments because producers regularly modify plastic surfaces to serve specific applications (i.e., Food, beverage, Cosmetics, etc.).

Mineral powder samples representative of the most abundant minerals in aquifers, i.e., goethite and kaolinite, were purchased from Sigma Aldrich. Quartz, feldspar, calcite, biotite and apatite samples were collected from the mineral collection at the Department of Geosciences and Natural Resource Management (IGN) at the University of Copenhagen. There, subsamples of a larger mineral were cut to access pristine, unweathered samples. The pristine sample was dry-milled for approx.10-30

6

128 min. After that, a powder suspension was made with ultra-pure Silex water. After ultra-sonication for

129 30 min, the mineral solution samples were wet sieved through a 20 µm mesh. After sieving, the

130 samples were oven-dried at 30°C for 24 h. The resulting powder was stored under dark, dry

131 conditions until further use. The mineral powders were then analyzed for major elemental and

132 mineralogical composition using X-ray fluorescence (XRF) and X-ray diffraction (XRD), respectively

133 (see below).

134 **2.2 Zetapotential & Hydrodynamic radius**

135 The Zeta potential (ZP) for polymers and minerals in 1 mM KCl was measured with the Stabino

136 (Colloid Metrics GmbH, Germany). The Stabino instrument measures streaming potential in a 10ml

137 PTFE chamber with an oscillating piston. The piston movement creates a mobile ion cloud around

138 the pistons surrounding it, forming a double layer that is set in motion. This oscillating ion cloud

139 generates voltage and is captured by two separate electrodes, which defines the streaming potential

140 of the solution as proportional to the zeta potential of the particles. The Stabino method is

141 advantageous for dense and polydisperse solutions as it can measure across a large particle size

142 range (0.3 nm– 300 µm) and particle concentrations up to 40vol%. Further, the optical properties of

143 the measurement liquid are not relevant for its measurement, unlike methods based on

144 electrophoresis.

145 Mineral powders were suspended in the desired electrolyte solution (1 mM), producing a suspension

146 of 100 mg/L for each mineral powder. To ensure full hydration of the mineral surface, the mixture

147 was shaken with an orbital shaker for 12 h and ultra-sonicated for 30 min before measuring its Zeta

148 potential (ZP).

149 The hydrodynamic radius was measured using dynamic light scattering (DLS) technology using

150 Nano-Flex II (Colloid Metrics GmbH, Germany), which applied the heterodyne 180° backscattering

151 principle. DLS measurements before and after the adsorption experiments add extra quantitative

7

152 and qualitative information on adsorption results when working with mineral and plastic particles.

153 The average of the intensity (D50) is reported in the following.

154 **2.3 Adsorption experiments**

155 To study the adsorption behavior of NP in batch experiments, a 20 ppm NP solution was prepared

156 by diluting a 100 ppm NP stock solution from above to the desired concentration using a one mM

157 KCl background electrolyte. The pH of that mixture was adjusted to 5 before the experimental start

158 using 0.05 mM HCl. The experiment was started by adding 20 mg of mineral powder to each 10 ml

159 vial to yield a mineral concentration of 2000 ppm, which is 100 times larger than the NP

160 concentration. There are currently no reliable measurements of NP occurrence in groundwater

161 environments. However, as minerals define the host material of rocks, the natural abundance of

162 minerals in groundwater logs surpasses the NP concentration by far.

163 Adsorption was detected spectrophotometrically using a Biotek EPOCH3 with UV cuvettes at IGN.

164 A wavelength of 220nm was most suitable for OD (optical density) measurements (see attachment)

165 of the different NP particles, as no interference with most minerals can be ensured. However, calcite

166 shows OD values beyond PS-PLAIN and PS-COOH and close to PS-NH2 at 20 ppm polymer

167 concentration. Thus, DLS provides additional evidence that clarifies contradictory (or unclear)

168 absorbance measurement data. To develop a background signal, the suspension of NP in 1 mM KCl

169 was analyzed before the addition of the minerals (starting concentration). After that, minerals were

170 added, and the suspension was left for 24 hours. During those 24 hours, the vials were placed on

171 an orbital shaker to ensure that the whole liquid was mixed in the vial. Upon conclusion of the

172 experiment, shaking was stopped, and the experimental vials were centrifuged for 20 minutes at

173 3000 rpm. The supernatant was removed by decantation. The supernatant's OD at 220 nm

174 wavelength was measured again at the final step.

175 The adsorption data are expressed as a percentage fraction. This fraction was calculated directly

176 from the OD measurements because, from the calibration curves (supplement), a linear relationship

8

177 is measured between OD and particle concentration at particle concentrations below 30 ppm (**Error!**

178 **Reference source not found.**). This approach is valid due to linearity below 30 ppm and has the

179 advantage of leaving out an intermediate calculation from OD to mg/L. At concentrations >30 ppm,

180 the OD of NP reaches saturation and takes a logarithmic shape. Consequently, interpretations of

181 experiments beyond 30 ppm are strongly biased. Thus, 20 ppm was used herein.

182 **2.4 Elemental and mineral composition**

183 The mineral powders were analyzed for major elemental composition using a handheld XRF

184 mounted in a certified portable workstation (HH-XRF, Innov-X Olympus Delta Premium 600 handheld

185 energy-dispersive XRF spectrometer) at IGN. Powder X-ray diffraction (PXRD) analysis further

186 checked the mineral composition using a Bruker-AXS D8 Advance diffractometer at IGN. This

187 instrument has a Cu X-ray tube, a primary beam Ge111 monochromator (wavelength 1.54059 Å),

188 and a silicon-strip LynxEye detector with an opening of 3.3°. The analyses were performed using the

189 Bragg-Brentano technique with a rotating sample holder, a fixed divergence of the primary beam of

190 0.25°, at 2θ angles between 5-90°, in steps of 0.02° and a measuring time of 4 seconds per step for

191 optimal statistical sample coverage. The qualitative evaluation of the sample mineral content was

192 performed using the Bruker DIFFRAC.EVA version 7.0 software and the built-in crystallography

193 database. The quantitative analyses were performed using the Rietveld refinement method and the

194 Bruker DIFFRAC.TOPAS version6 software and structure files imported from the Inorganic Crystal

195 Structure Database (ICSD,(Bergerhoff et al. 1983). The PXRD profiles were defined by fundamental

196 parameters calibrated using a powder CeO_2 standard with an average crystallite size of 595 nm.

197 **2.5 Imaging**

198 After centrifugation, the solid mineral samples remaining in the vials were inspected under a He-ion

199 microscope (Orion NanoFAB, Carl Zeiss) at the Mads Clausen Institute (MCI), University of Southern

200 Denmark (SDU) to visualize their association with NP. The beam energy was set to 30 keV, with a

201 probe current ranging from 0.1 to 0.3 pA. Before imaging, no conductive coatings were applied to

202 the samples to preserve the sample surface information. Charge compensation was ensured through

203 a low-energy electron beam (flood gun, 433 eV) directed at the sample.

2.6 Interaction energies (DLVO)

205 Theoretical interaction energies were calculated based on classical DLVO using a sphere-plate

206 relationship according to the equations provided, i.e., (Israelachvili 2011a) and (Petosa et al. 2010).

207 Van der Waals forces (VDW) were calculated by:

$$208 \quad VDW = -\frac{A_{123} * a_p}{6h(1 + \frac{h}{\lambda})}$$

209 Table A.1 in the supplementary section provides details on mineral- specific Hamaker constants

210 where A_{123} is the Hamaker constant between the polymer and respective mineral in water. a_p is the

211 particle radius, assuming 100 nm as the nominal particle diameter. h is the separation length

212 between the sphere, and λ is the characteristic retardation wavelength. Retardation limits the range

213 of the VDW forces at larger separation distances, as at larger separation distances, the polarization

214 of dipoles is less correlated. (Henry et al. 2012).

215 The electric double-layer force component (EDL) was calculated as follows:

$$216 \quad EDL = 64\pi\varepsilon_0\varepsilon a_p\left(\frac{k_BT}{ze}\right)^2 \tanh\left[\frac{(ze\zeta_1)}{(4k_BT)}\right]\tanh\left[\frac{(ze\zeta_2)}{(4k_BT)}\right]exp(-\kappa h)$$

217   With k being the Debye length estimated by:

$$218 \quad \kappa = \left(\frac{2 * IS * e^2 * NA * 1000}{\varepsilon_0\varepsilon k_BT}\right)^{1/2}$$

219 Where ε_0= dielectric permittivity in vacuum (8.8541878128E-12 C^2 J^{-1} m^{-1}), $\varepsilon =$ dielectric constant in

220 water (78.54 at 25°C), a_p= particle radius, k_B= Boltzmann constant (1.38E-23 m^2 kg s^{-2} K^{-1}), T=

221 Temperature in Kelvin, z=ion valency of the solution, e= elementary charge constant (-1.60E-19

10

222   C),ζ_1 and ζ_2 are the Zeta potential of the polymer and mineral, respectively. IS is the ionic

223   concentration of the solution (here 1 mM) and NA= Avogados number (6.02E+23 particles M^{-1}).

224   Finally, the complete interaction is calculated by:

225 $$VDLVO = VDW + EDL$$

226   given in k_BT units.

227

11

3. Results & Discussion

3.1 Mineral origin and their relevance for groundwater aquifer systems

Upon entering the subsurface, NPs come into close contact with the mineral composition of the host materials. Among the hydrological characteristics (such as pore size and porosity), these mineral properties are crucial in governing the fate and transport of nanoparticles (NPs) in subsurface environments. Geological evolution defines a groundwater aquifer's mineral constituents, making the mineral composition of individual aquifers highly dependent on regional geological history. Simplifying this complex natural composition to just a few minerals is challenging. Nevertheless, a few minerals can be considered abundant in most terrestrial aquifers on a global scale due to their specific rock-forming mechanisms. Those are quartz and other rock-forming silicates, clay minerals from the smectite and kaolinite groups and illite, iron oxides such as goethite and hematite as well as carbonates. A selection of seven minerals is included in this study, and an overview of their respective aquifer abundance, as well as rock formation condition, is listed in Table 1. Among those chosen minerals, quartz, feldspar, goethite, kaolinite, and calcite are by far the most abundant.

Mineral	Geological environment (by abundance)	Formation	Aquifer type (by highest abundance)
Quartz	most rock formations, water-yielding units	As part of crust formation (e.g., crystallization in igneous rocks, crystallized from metamorphic fluids)	porous media, fractured rocks, karstic systems
Goethite	high abundance on earth in aquatic environments (lakes, soils, swamps, porous media)	Weathering product of iron-rich minerals	porous media, high-yielding aquifers
Apatite	Igneous rocks (i.e., granite), metamorphic (i.e., gneiss), sedimentary rocks as erosive-reformed products (i.e. organic marine deposits)	Crystallization in igneous rocks, precipitation in aquatic environments, metamorphic formation	porous media & fractured rocks
Biotite	Magmatic and metamorphic rocks, 2:1 phyllosilicate	Crystallization in igneous rocks, metamorphic processes	fractured igneous aquifers
Kaolinite	Type 1:1 clay low abundance in ocean sediments and a high abundance in the crust	Weathered granitic rocks	porous media and weathered soils

12

Feldspar	60% of Earth's crust, igneous, metamorphic	Precipitation from magma, metamorphic formation	porous media, fractured rocks
Calcite	most stable calcium carbonate mineral under atmospheric surface conditions, main constitute of limestones and marble	Precipitation in aqueous environments, diagenetic conditions.	sedimentary porous media, Karstic systems, limestone fractured aquifers

242 *Table 1. Mineral description and their geological abundance in Earth´s environmental systems,*

243 *major formation properties (Klein and Dutrow 2007), and relevance for different types of aquifer*

244 *systems. As those minerals are abundant on Earth, their corresponding occurrence in all aquifer*

245 *systems is given.*

246 **3.2 Mineral inspection and quality**

247 Mineral impurities are common in natural settings. While naturally occurring impurities on minerals

248 may dramatically alter the transport characteristics of NPs, it had to be ensured that the minerals

249 used herein are of high quality and purity.
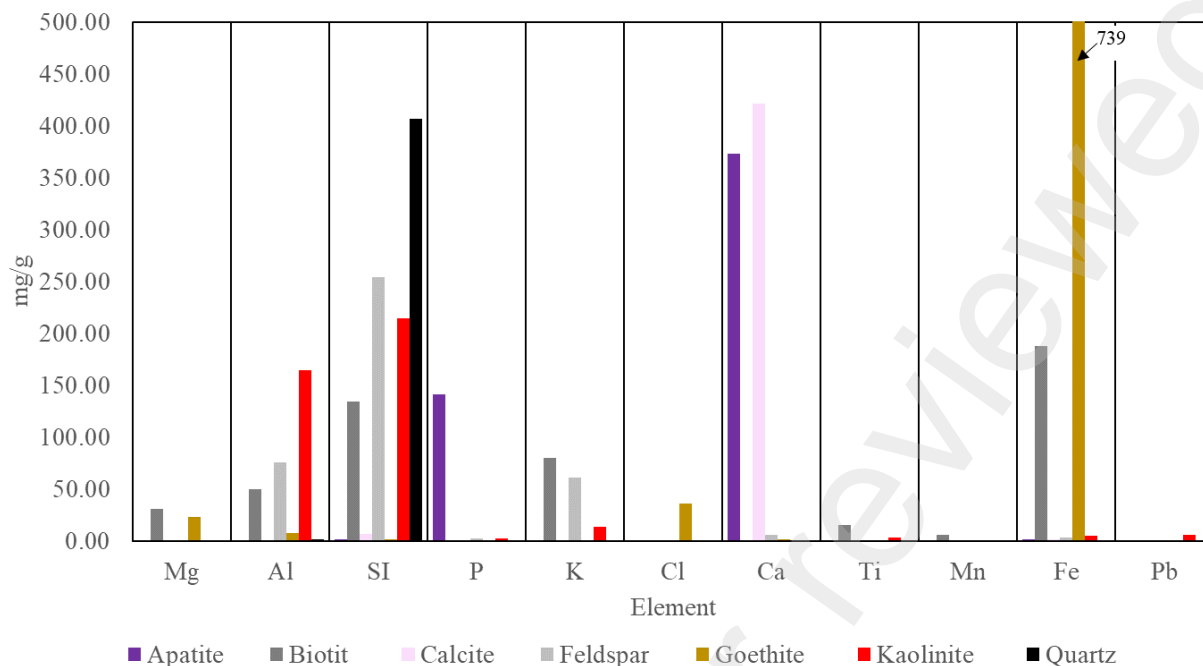

Fig. 1. Element contents of mineral samples used (color coded) determined by XRF. Th). Small amounts of Cl⁻ and Mg²⁺ in goethite are most likely a result of pre-washing of the mineral during industrial production.

| Mineral	PXRD results
Quartz	quartz, SiO_2 (98.08%); orthoclase, $KAISi_3O_8$ (1.92%)
Goethite	pure goethite, $FeO(OH)$
Apatite	hydroxylapatite, $Ca_5(PO_4)_3(OH)$, pure
Biotite	biotite, $K(Mg,Fe)_3(AISi_3O_{10})(OH)_2$, pure
Kaolinite	kaolinite, $Al_2Si_2O_5(OH)_4$ (87.5%), quartz, SiO_2 (9.4%), plumbogummite, $PbAl_3(PO_4)(PO_3OH)(OH)_6$ (3.10%)
Feldspar	antiperthite, albite, $(KAISi_3O_8)$ (61.9%), microcline, $(NaAISi_3O_8)$ (38.1%),
Calcite	calcite, $CaCO_3$ (99.6%) and quartz, SiO_2 (0.4 %)

Table 2. Summary of PXRD mineral compositions determined by Rietveld qualitative analysis (using the Bruker.TOPAS software). Corresponding PXRD diagrams can be found in supplementary material. The quantitative results are expressed in wt %

14

257 The mineral composition of the samples applied in this study is detailed in Table 2 and their chemical

258 composition measured by XRF in Fig. 1. Apatite assembles major contents of phosphorous and

259 calcium ions, and the XRD confirms it as hydroxylapatite. A more complex elemental composition

260 shows biotite containing a mixture of Si, Al, Fe, Mg and K ions and its purity is confirmed by PXRD.

261 The purity of feldspar (Al, Si, Na, K), quartz (Si) and calcite (Ca, and trace amounts of Si) is confirmed

262 by both PXRD and XRF measurements. The latter measuring the elements with electron number

263 greater than 11, thus not registering Na.

264 The kaolinite sample shows a small admixture of quartz and a mineral belonging to the

265 plumbogummite family, which explains the small amount of Pb and P found by XRF. Small amounts

266 of K and Fe, also detected by XRF, are normally adsorbed to kaolinite and point towards the origin

267 of kaolinite in the zone of rock and ore metamorphism (**Error! Reference source not found.Error!**

268 **Reference source not found.**). In goethite, XRF shows a distinguishable amount of Cl. This may

269 occur when industrially produced goethite is washed clean with acid, and Cl- ions remain on the

270 surface.

271 **3.3 Polymer and Mineral ZP as a function of pH**

272 In abiotic settings, the ZP of particles and minerals is considered a good indicator for deducting

273 adsorption properties. The value for ZP is unique depending on particle surface chemistry, different

274 ion types, and the electrolytic solution's overall ionic strength (IS) (Bhattacharjee, 2016). A 10%

275 measurement error on the value of ZP may be expected, while potential measurement uncertainty

276 is increased close to the iso-electric point (IEP) (Kosmulski, 2009; Nobbmann, 2017).

277
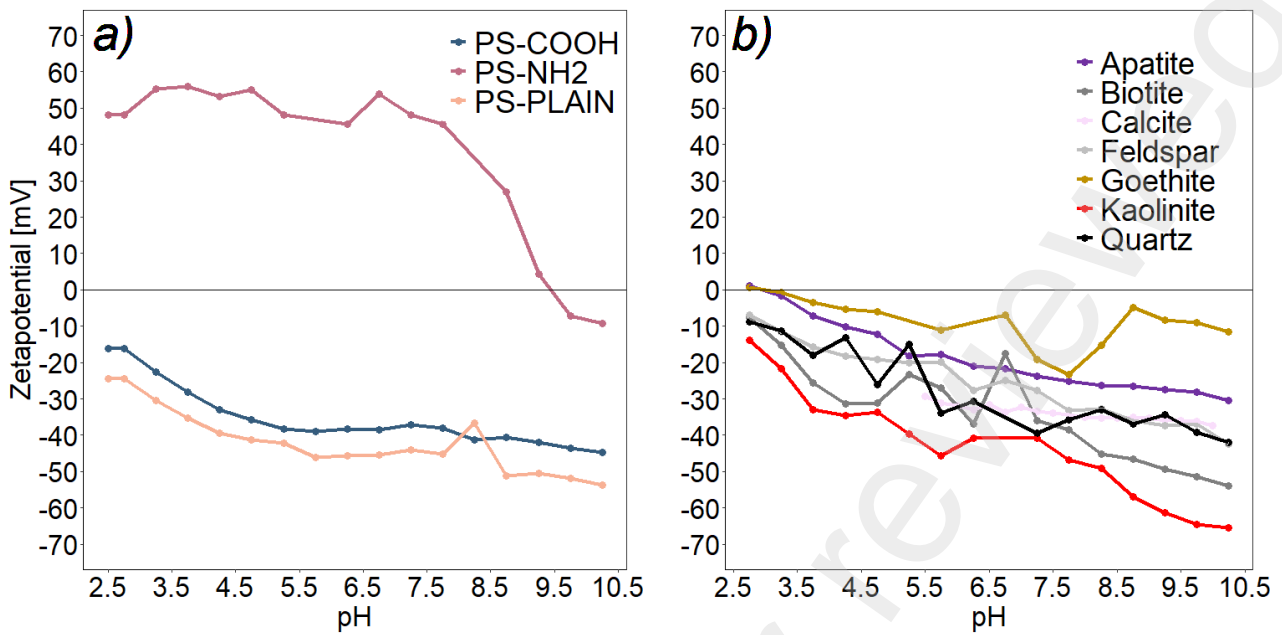

Fig. 2. ZP across pH in 1 mM KCL experimental solution. a) for non-coated Polystyrene (PS-PLAIN),
for carboxylated polystyrene (PS-COOH), and amine-coated polystyrene (PS-NH2) particles and b)
for minerals used in this study. Overall, the ZP decreases with decreasing pH.**Error! Reference
source not found.**The ZP of polystyrene (PS) with various surface coatings and minerals is shown
as a function of pH (Fig. 2). PS-PLAIN and PS-COOH particles and all minerals obtain a negative
charge, contrary to the amine-coated PS, throughout a wide pH range (Fig. 2). At conditions relevant
to the natural environment, i.e., pH from 4.5 to 8.5, charges vary between approximately - 40 and -
10 mV, respectively, with the exception of PS-NH2 that remains positively charged. Protonation
(lowering pH) or deprotonation (increasing pH) of a particle surface moves the ZP towards 0 mV with
decreasing pH and vice versa when metal ions are associated at the particle surface (Kirby and
Hasselbrink 2004). Protonation and deprotonation have a minor effect on the ZP of calcite, which is
unstable at low pH. For calcite, charge only indirectly relates to pH as the calcite surface is dominated
by CO_3^{2-} ion between pH 5 and 11 and is thus negatively charged. The surface composition is not
controlled by pH but by Ca^{2+} and CO_3^{2-} availability in solution. Therefore, pH affects ZP on the surface
of calcite only at constant CO_2 pressure where Ca^{2+} and pH are related (Al Mahrouqi et al. 2017).

16

293 The partial pressure of CO_2 was not constant during the measurements presented here. Therefore

294 calcite was unstable (dissolved), and ZP values were discarded below pH5.5.

295 For PS-NH2, the influence of OH- groups at the surface causes a reversed trend. Protonation of

296 amino groups prevails across the entire pH range. Goethite has negative ZPs across the pH range,

297 and an IEP around 8 is not reached. Goethite´s IEP may vary between pH 5- 9 (Kosmulski 2009;

298 Shrimali et al. 2016) Depending on mineral impurities. Scaratti et al. (2018) reported similar results

299 to our measurements for α-FeOOH (goethite) and attributed it to the surface-adsorbed anionic

300 species, e.g. CO_3^{2-}, SO_4^{3-} . Those anionic species are thus likely to reduce naturally occurring

301 goethite IEP far below pH 8. XRF analysis identified the presence of Cl- ions associated with the

302 goethite used herein (Fig. 1). This indicates that the commercial goethite sample was synthesized

303 with Cl- salts instead of NH_4^+ salts. Chloride shows a higher affinity for ion oxides and cannot

304 exchange OH- groups as easily, producing negative ZP at lower pH. (Ahmed and Maksimov 1968)

305 Therefore, the streaming potential method applied at the Stabino system captures the minor

306 presence of Cl- ions at the surface. Different streaming potential methods directing liquid over a

307 porous sample surface, or the more general electrophoresis method based on current exciting the

308 sample may not capture such minor impurities.

309 Apatite´s ZP and IEP strongly depend on the ion type in the background solution and the type of

310 apatite and elemental impurities. Indeed, IEPs vary between pH 8 in a KNO_3 solution for

311 hydroxyapatite down to pH 6 for fluorapatite (Somasundaran and Wang 1984). A recent study

312 reported IEP as low as pH 3.5 at ten mM KCl (Zhou et al. 2020). The latter study aligns with our

313 measurements at 1 mM KCl. Apatite has the potential to release Ca^{2+} ions to the surrounding solution

314 as a function of pH, which is shown not to affect the overall electric properties of the apatite (Zhou

315 et al. 2020). Biotite and kaolinite ZPs align with measurements reported for 1 mM KCl (Filippov et al.

316 2016).
17

320 **3.4 Mineral- Polymer adsorption**

321 The interaction of NP with minerals can be interpreted from measuring NP concentrations in

322 supernatants before and after a mineral amendment to a suspension. The results of the

323 spectrophotometrically obtained supernatant NP concentrations expressed as a %- fraction of the

324 original concentration are shown in Fig. 4. A value of 100 % indicated that all PS particles were

325 absorbed to the mineral. Thus, the PS was withdrawn from the supernatant and undetected. DLS-

326 particle sizes of the same supernatant are shown in Table 3. Using this measurement, additional

327 information was gained on particle aggregation (size increase), destruction (size decrease), or

328 adsorption and settling (no size detection).

329 Overall, DLS sizes and absorbance measurements agreed, meaning that when no adsorption was

330 spectrophotometrically detected, the DLS size in the supernatant solution were close to the size of

331 the original polymer (Table 3).

18

332
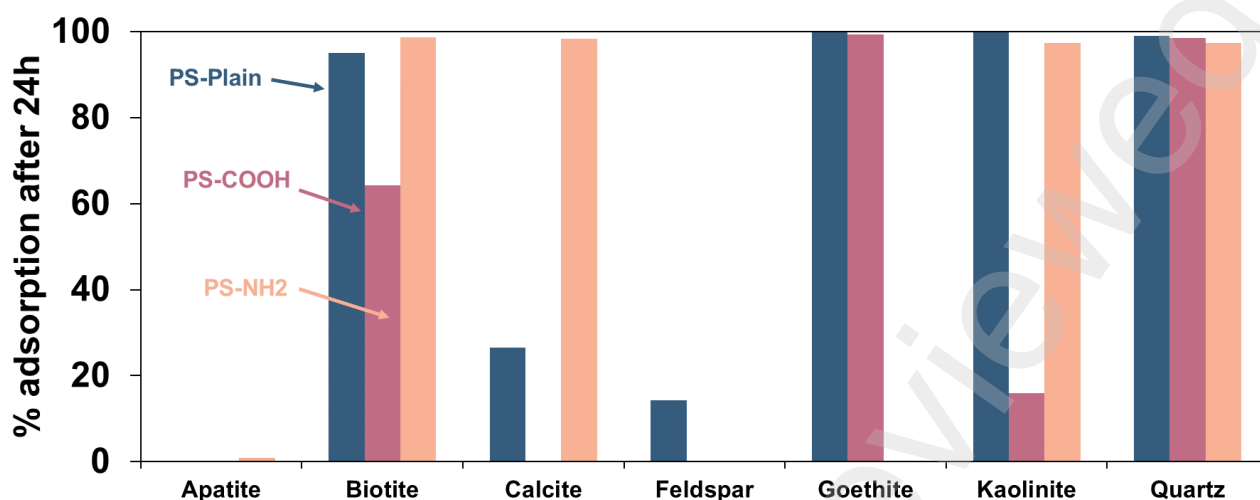

Fig. 4. Results of 24-hour adsorption experiments at pH5. Changes in NP concentrations in the

supernatant are expressed in % change compared to the starting concentration. If no adsorption

exists, the adsorption percentage yields 0%, while if no NPs are present, the adsorption yields

100%.

Adsorption behavior varies between mineral and NP types (Fig. 4). Often, the presence of PS particles was indicated by D50 occurring at around 100 nm, which is the original PS size. Size fractions above the background DLS- D50 of PS indicated the formation of heteroaggregates that remained in the solution after centrifugation.

DLS-Peak	PS-PLAIN 1st	2nd	3rd	PS-COOH 1st	2nd	3rd	PS-NH2 1st	2nd	3rd
pure particle	140.6±44			85.4±21			90.2±28.1

*Table 3. DLS sizes for pure NP in 1 mM KCl as well as the decanted solution. The measurements from the decanted solution represent a potential NP-mineral aggregate formed. If present, the 1st, 2nd, and 3rd refer to multiple peaks in the DLS signal. No adsorption is indicated if a single peak is observed screening the original particle size. Those are highlighted in **bold**. Partly adsorption is indicated when a fraction of the original particle size is measured in solution. In contrast, adsorption is indicated when only larger sizes or no observation can be made (due to gravitational particle settlement). Values highlighted in red give contradictory information compared to absorbance measurements.*

Generally, the adsorption behavior can be explained by charge-driven interactions, where oppositely charged materials attract one another. Apatite and feldspar showed potential for the lowest adsorption affinity for PS independent of their surface coating, which was expressed in an adsorption percentage close to 0%. This was confirmed by DLS for PS-NH2, where the D50 of 86nm was recorded close to the PS-NH2 original size (Table 3).

356 For PS-PLAIN-Kaolinite and PS-NH2-Kaolinte, effective adsorption was measured (close to 100%),

357 while two DLS peaks at 594nm and 1541nm for the PS-PLAIN-Kaolinite solution and a single peak

358 at 2566nm for the PS-NH2-Kaolinite solution were detected. This suggested heteroaggregation (DLS

359 particle size increase). The lack of an absorbance signal can be attributed to the shielding of Kaolinite

360 deposition at the PS particle surface.

361 A further advantage of combining DLS with absorbance measurements is shown for PS-NH2-apatite,

362 PS-PLAIN—biotite, PS-NH2—goethite, PS-PLAIN—quartz, and PS-COOH—quartz (Table 3, red

363 highlighted). For example, the absorbance method suggests no adsorption (close to 0%) for Apatite

364 and PS-NH2, while a larger-sized primary and secondary DLS peak at 177nm and 652nm exists for

365 these particles, respectively.

366 *3.4.1 Apatite*

367 No adsorption of PS-PLAIN and PS-COOH on the surface of apatite was observed, which was

368 confirmed by DLS, showing the presence of a single peak close to the original polymer size. Despite

369 the opposite charge between the apatite´s surface and the PS-NH2 as well as theoretical DLVO

370 calculations, neither adsorption is suggested based on the absorbance measurements. However,

371 DLS does not confirm these results. The occurrence of two major peaks, with the first peak

372 approximately double the original polymer size and the second peak at 652nm, suggests aggregation

373 processes have occurred. The release of Ca^{2+} ions from the apatite surface may cause

374 homoaggregation by forming calcium amides and, hence, bridge NH2 functionalized particles

375 (Speight et al. 2019). The visual inspection of the supernatant with HIM indicates such a process,

376 where larger homoaggregates are shown among single particle appearances (**Error! Reference**

377 **source not found.**). However, those homoaggregates do not explain a D50 of 652nm as their size

378 in the HIM image is below that value. The HIM images also show heteroaggregates among the PS-

379 NH2 homoaggregates. Those are approximately of the size of the D50 (**Error! Reference source**

380 **not found.**). Thus, a combination of homo- and heteroaggregates can explain the second observed

381 DLS peak. Interestingly, Zhu et al. (2003) found only a very small deposition of apatite onto NH2

21

382 surfaces at pH <7.5 using Quartz-Crystal Microbalance with Dissipation (QCMD) measurements.

383 There, a two-stage process involving EDL interaction (pH > 7) and hydrogen bonding of NH2 head

384 groups (NH3) (ph<7) is proposed. Unfortunately, neither the pH of the decadent solution or the

385 elemental composition was measured to confirm such a process. Hence, the underlying mechanism

386 can only be speculated upon, while HIM images and DLS sizes prove that aggregation occurred.

387
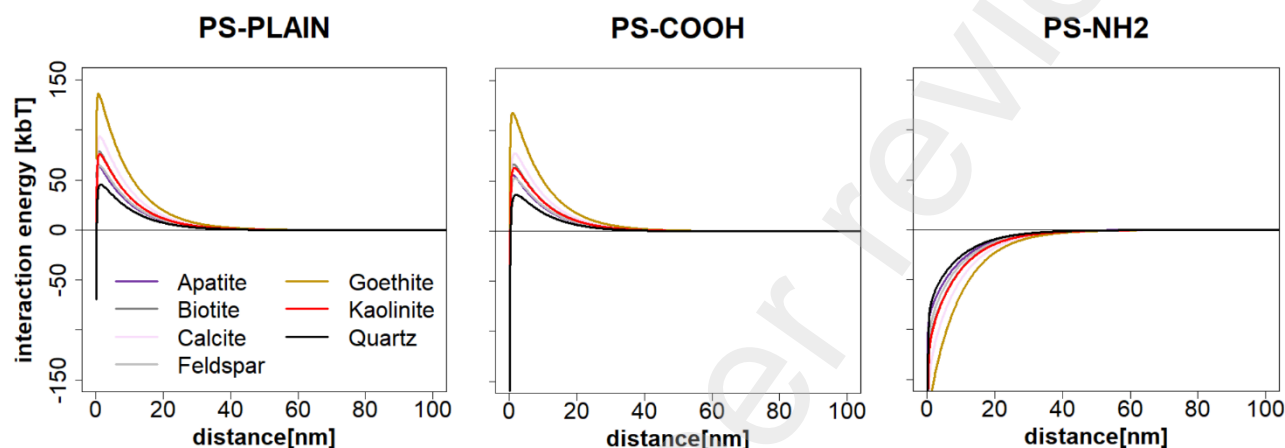

Fig. 5. Theoretical sphere-plate DLVO interaction energies at pH 5.25 in a one mM KCl solution.

389 *PS-PLAIN and PS-COOH show a strong repulsive barrier for all mineral types, while PS-NH2*

390 *shows a strong, attractive force component. DLVO can only partly reproduce adsorption*

391 *observation, and it can be concluded that its predictive quality fails for more complex mineral*

392 *compositions.*

393 *3.4.2 Feldspar*

394 The adsorption results and DLS results align and show that NPs do not adsorb onto feldspar as well

395 as reflect the original D50 particle size. From DLVO, adsorption between PS-NH2 particles and

396 feldspar was expected (Fig. 5). Yet, the lack of adsorption between PS-NH2 and feldspar may be

397 explained by surface free energies (Lewis-Acid base), which create a steric force component. In the

398 presence of amino groups, feldspar increases surface hydrophobicity (Karagüzel et al. 2005),

399 preventing the attachment of amine- coated PS. Moreover, surface adsorption onto feldspar may be

400 influenced by the configuration of the Lewis-acid base interaction energies. The same study shows

22

401 that upon grinding, the feldspar surface mainly becomes a basal plane surface (-OH endings), where

402 the Lewis-electron acceptor component (y_s^+) is larger than the Lewis-electron donor component (y_s^-).

403 Consequently, PS-NH2 is less likely to adsorb onto the mineral surface.

404 *3.4.3 Biotite*

405 Based on absorbance measurements, adsorption of different magnitudes was suggested between

406 biotite and all NP types (i.e., PS-PLAIN and PS-NH2 nearly 100%) (Fig. 4). Helium-ion microscope

407 images also showed PS-PLAIN-biotite aggregates (Fig. 6). General DLVO calculations suggests that

408 only adsorption of PS-NH2 on biotite is due to opposite charge interaction (Fig. 5). However, the

409 DLS measurements show particles around the nominal diameter of PS-PLAIN in solution. The DLS

410 of the PS-COOH groups show a primary peak at 258 nm and a secondary peak at ~65nm, which is

411 close to the nominal diameter (Table 3). The presence of two size fractions in PS-NH2 particles is

412 also observed (7.8nm and 1682nm). Potentially, net-negative charged biotite particles adsorb onto

413 positive charged PS-NH2 particles, forming hetero-aggregates and thus shielding the actual polymer

414 for the absorbance signal. This would explain the low spectrophotometric detection and the presence

415 of a larger size fraction in the supernatant. Despite the strong repulsive barrier present (Fig. 5), biotite

416 may still attach NP via its positive Mg+ and Al+ edges. Bray et al. 2014 show how metal release

417 mechanisms of biotite strongly depend on the pH of the solution, while the net charge of the biotite

418 surface is unaffected. More specifically, they show that around pH 5 (experimental pH used herein),

419 biotite contains only low amounts of Mg2+, while Al+ remains exposed on the edges. Additionally.,

420 it is shown that biotite grain edges exceed the reactivity of the basal planes between 71-131 times

421 (Hodson 2006). Hence, PS-PLAIN may adsorb onto the positively charged edges of the biotite

422 mineral. A slightly modified mechanism can explain the observed adsorption for PS-COOH NPs.

423 Here, divalent positive Mg2+ ions bridge the COOH groups at the polymer surface and cause

424 adsorption. This mechanism is well known for organic matter in the presence of COOH groups

425 (Adusei-Gyamfi et al. 2019). But it is less effective for Mg2+ due to the affinity for Mg to water, where

23

426 COOH groups cannot dehydrate Mg effectively (Carter-Fenk et al. 2021) yielding less effective

427 bridging.

428 *3.4.4 Calcite*

429 From the absorbance measurements, calcite- PS interaction was considered charge driven, as

430 similar charged PS-PLAIN and PS-COOH remained in solution, while PS-NH2 particles were fully

431 absorbed. This process was largely confirmed from the DLS measurements, where the original

432 sizes of the plain and COOH polymers are still in solution. The PS-NH2 sample shows three

433 peaks, with the largest occurring at 648 nm and a second even larger peak at 4588 nm. This

434 suggests the occurrence of aggregation processes. HIM inspection does not show clear PS-NH2-

435 calcite aggregates formations, but rather points towards homoaggregation of PS-NH2 (**Error!**

436 **Reference source not found.**). The presence of divalent ions Ca^{2+} in solution can be an effective

437 coagulant if the concentration is close to the critical coagulation concentration (CCC). This

438 suggests that calcite is dissolved and the release of Ca^{2+} into solution provoked homoaggregation

439 of the particles causing a large range of DLS sizes.

440 3.4.5 Kaolinite

441 The 1:1 clay kaolinite effectively adsorbs PS-PLAIN and PS-NH2, while it does not effectively adsorb

442 PS-COOH. The adsorption behavior for PS-NH2 is predicted with DLVO (Fig. 5) as well as confirmed

443 by DLS measurements (Table 3). In contrast, PS-PLAIN and PS-COOH show modified adsorption.

444 Kaolinite has a high charge heterogeneity with net-negative charge but carries positively charged

445 Al+ ions on the edges, which, depending on pH and IS, initiates aggregation processes. The

446 increasing role of positive charge groups at the kaolinite surface is shown at pH below 6- 6.5 and at

447 IS of 1 mM NaCl (Tombácz and Szekeres 2006). While ZP under current study conditions of pH 5.5

448 is net negative (Fig. 2), positive chargers are present.   Consequently, PS-PLAIN particles without

449 any surfactant will be attracted to the positive sites and thus get adsorbed to the kaolinite matrix, that

450 is also expressed in the DLS primary sizes of 594nm. DLVO calculations cannot confirm that

451 process, as it does not account for charge heterogeneities. Adsorption to kaolinite is low to PS-

24

452   COOH likely due to the strong steric force component introduced by the -COOH groups on the

453   polymer. Those stabilize the polymer against aggregation, which is also confirmed by the DLS

454   measurements.

455   3.4.6 Goethite

456   Goethite showed a high affinity for negatively charged particles of PS-PLAIN and PS-COOH, while

457   no adsorption to the PS-NH2 particles occurred. From the DLS measurements, a larger fraction was

458   still present in the PS-PLAIN and PS-COOH of 592nm and 1396, respectively. This suggests either

459   homoaggregates or heteroaggregates between iron hydroxyl-oxide and polymers. No absorbance is

460   detected at the wavelength of 220nm from the absorbance spectra of goethite (**Error! Reference**

461   **source not found.**). This suggests that goethite or an iron species coats the polymer surface and

462   shields it when absorbance is measured. Hence, no absorbance at 220nm was detected. Based on

463   our ZP measurements and the consequent DLVO calculations, such interactions are not suggested

464   (as discussed above). Nonetheless, it is commonly observed that attractive electrostatic interactions

465   between iron oxides and negatively charged polymers occur (i.e., Alimi et al. 2018; Zhang et al.

466   2020). The visualization of such hetero-aggregates confirms the adsorption between the PS-PLAIN

467   and goethite (Fig. 6A and **Error! Reference source not found.**). No adsorption occurred between

468   goethite and PS-NH2 due to similar charges for the two phases. Nonetheless, DLS measurements

469   of the PS-NH2- goethite supernatant show a peak at 298nm (Table 3) and HIM imaging shows

470   clearly homoaggregates (**Error! Reference source not found.**), evidently pointing towards

471   homoaggregate not adsorbed to the mineral phase. Different mechanisms may cause the release of

472   iron from goethite in the presence of organic molecules. Particularly at lower pH <8, the release of

473   Fe(III) species from the surface is common (Li et al. 2022). Those may attach to the surface of the

474   PS-NH2 particles and cause a partial aggregation, which the DLS detects (Table 3) and HIM imaging

475   confirms (**Error! Reference source not found.**).

25

A) PS-PLAIN & Goethite   B) PS-PLAIN & Biotit   C) PS-PLAIN & Quarz

476
Fig. 6. HIM image of the mineral-plastic interface in the pellet.

478   3.4.7 Quartz

479   Quartz showed effective adsorption to all NPs despite the similarly charged surfaces of PS-PLAIN

480   and PS-COOH, while this was expected only for PS-NH2 according to the DLVO. The measured

481   DLS sizes show a small size increase of the PS-PLAIN and PS-COOH supernatant, while no signal

482   was detected for the PS-NH2 supernatant. The latter evidently pointed towards an effective

483   adsorption of PS-NH2 and was confirmed by HIM images (**Error! Reference source not found.**A).

484   Furthermore, the HIM images of the pellet and supernatant for PS-PLAIN and PS-COOH with quartz

485   can explain the observed discrepancy between absorbance - and DLS measurements. Adsorption

486   of PS-Plain to the quartz pellet is indicated by HIM images (Fig. 6). HIM imaging did not detect PS-

487   PLAIN and PS-COOH NPs in the supernatant (**Error! Reference source not found.**B and C), but

488   quartz particles below 1 µm were visible. Thus, the DLS sizes of 183 nm and 164 nm for the PS-

489   PLAIN and PS-COOH supernatants are misleading and reflect suspended quartz particles, not NPs.

490   The attraction between PS-PLAIN and PS-COOH as exemplified in Fig. 6, can be explained by the

491   small amount of orthoclase measured by PXRD (Table 2). Orthoclase has Al^{3+} sides, with local

492   positive charges, which create attractive adsorption conditions for PS-PLAIN and PS-COOH.

493   Alternative processes can take place at the quartz surface which can explain such unexpected

494   adsorption behavior. Breaking Si-O bonds upon grinding, the oxide surface becomes unsaturated

26

495 and in contact with water becomes hydroxylated which changes its surface physiochemical

496 properties. When PS and particular PS-COOH are present in that water, the polymers OH⁻ ending

497 may absorb the unsaturated endings (Zheng et al. 2024). However, such a process is speculative

498 and may be interfered with by water molecules, creating a hydration layer on the quartz surface (non-

499 DLVO force "solvation") and thus creating a near-surface repulsive energy barrier. To investigate

500 such a process, a different study with a different hypothesis needs to be set up.

501 The interactions between different functionalized NPs and the minerals evaluated in this manuscript

502 is presented in a conceptual manner to display the processes described in this study in Fig. 7.
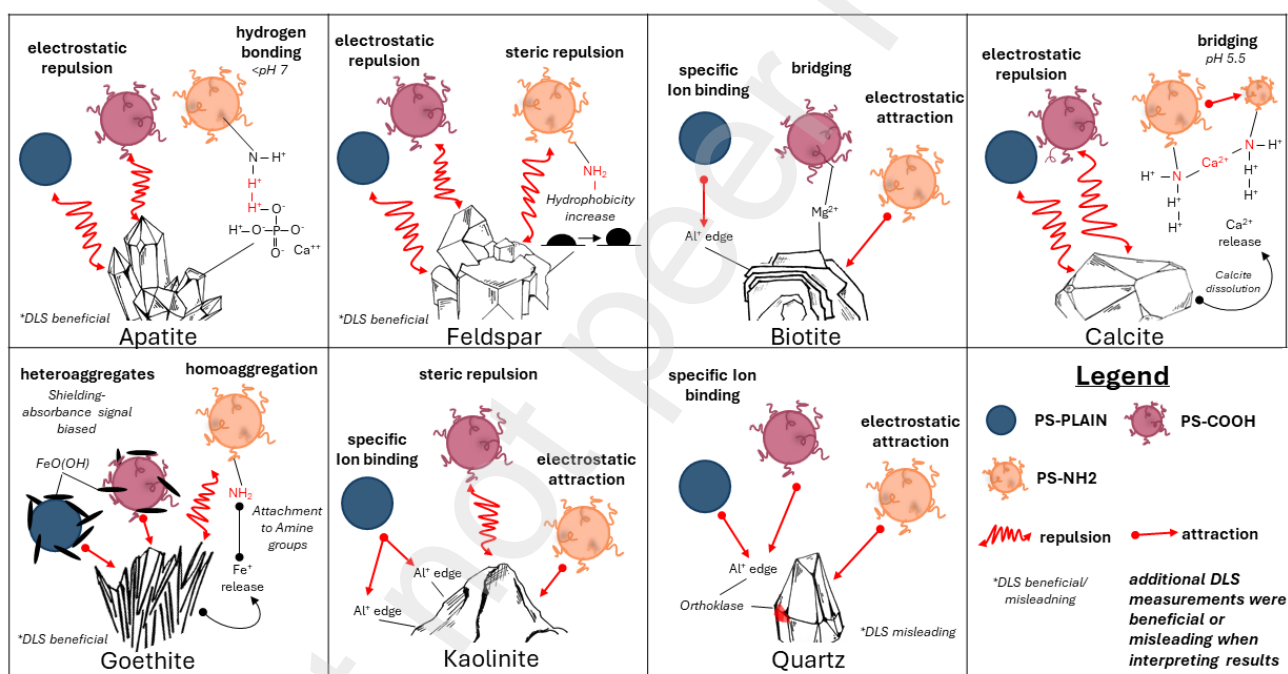

503

504 *Fig. 7. Conceptual summary of adsorption results of different functionalized nanoplastic with*

505 *various minerals. If not otherwise stated, electrostatic interaction was not dominant, and other*

506 *processes may be more relevant. Additional DLS measurements of the supernatant were*

507 *beneficial for indicated minerals to explore mechanisms between NPs and minerals.*

4. Implications and Conclusion

Nanoparticles released into the aquatic environment interact with minerals in the subsurface environment. Here, we study the interaction of different surface-modified polystyrene nanospheres with the most abundant mineral species in terrestrial freshwater environments. The interaction is explored using batch adsorption experiments in combination with DLS measurements, visual inspection using HIM and compared with theoretical DLVO calculations. We show that mineral-specific interactions with PS particles exist. The interaction is largely charge-driven as DLVO theory overall aligns well with the observation. However, theoretical calculations fail to predict interactions when a more complex mineralogical structure is present and specific ion binding and bridging processes dominate the interaction.

Main findings include:

- Zeta potential varies greatly with pH for minerals and nanoplastics, while under environmentally relevant pH conditions (pH 4.5-8), stronger negative charges are predominant for both minerals and PS

- The interaction between minerals and plastic is mainly charge-driven, where Zeta potential is a good indicator of their interaction behavior

- Clay minerals may not be efficient in removing NP particles from the liquid phase under environmentally relevant pH conditions

- More complex interaction is often associated with -NH$_2$ groups at the polymer surface

- Bridging interaction occurs when Ca-containing minerals are present, minerals with Al- edges or Fe- release drive specific ion binding interaction, and Phosphor induces hydrogen bonding mechanisms

Our findings highlight implications for the fate and transport processes of nanoplastic in terrestrial freshwater environments. The mineral interaction with nanoplastic particles impacts nutrient-rich interfaces at the hyporheic zone or wetlands, groundwater discharge zones in agriculturally impacted

28

534 streams or lakes, redox boundaries in the aquifer, recharge areas near coastal saltwater wedges,

535 and wastewater treatment plants.

536 In future studies, mineral-plastic interaction should be studied more systematically regarding aquifer

537 and groundwater-related systems' biogeochemical and mineral complexity. This study indicates that

538 biogeochemical and mineralogical composition controls the attachment and release of NP in

539 porewaters, and therefore determining its transport in aquifers.
